We investigate paradigmatic representations of word context in the domain of unsupervised part of speech induction. Paradigmatic representations of word context are based on potential substitutes of a word in contrast to syntagmatic representations based on properties of neighboring words. We demonstrate paradigmatic representations within two frameworks: (1) context clustering and (2) co-occurrence modeling. In context clustering we cluster word contexts based on the potential substitutes and they reveal a grouping that largely match the traditional part of speech boundaries. In co-occurrence modelling we construct a Euclidean embedding that models the co-occurrence of word types and their contexts. Clustering the points that correspond to word types in the Euclidean embedding gives state-of-the-art results in unsupervised part of speech induction, including 80% many-to-one accuracy on the Penn Treebank and significant improvements on 17 out of 19 corpora in 15 languages.

1. Introduction

Grammar rules apply not to individual words (e.g. dog, eat) but to part-of-speech categories (e.g. noun, verb). Thus learning part-of-speech categories (also known as lexical or syntactic categories) is one of the fundamental problems in language acquisition.

Linguists identify part-of-speech categories based on semantic, syntactic, and morphological properties of words. There is also evidence that children use prosodic and phonological features to bootstrap part-of-speech category acquisition (Ambridge and Lieven 2011). However there is as yet no satisfactory computational model that match human performance. Thus identifying the best set of features and best learning algorithms for part-of-speech induction is still an open problem.

Relationships between linguistic units can be classified into two types: syntagmatic (concerning positioning), and paradigmatic (concerning substitution). Syntagmatic relations determine which units can combine to create larger groups and paradigmatic relations determine which units can be substituted for one another. Figure 1 illustrates the paradigmatic vs syntagmatic axes for words in a simple sentence and their possible substitutes.

Part-of-speech categories represent groups of words that can be substituted for one another without altering the grammaticality of a sentence. In this paper we explore models of part-of-

Syntagmatic vs. paradigmatic axes for words in a simple sentence (Chandler 2007).

speech induction based on potential substitutes of words. We build *substitute word distributions* for each position in the text which specify the probability of every vocabulary word in that position. Table 1 gives substitute distributions for an example sentence.

Table 1
The substitute word distributions (with probabilities in parentheses) for some of the positions in the example sentence “*Pierre Vinken, 61 years old, will join the board as a nonexecutive director Nov. 29.*” based on an n-gram language model.

will:	<i>will</i> (0.9985), <i>would</i> (0.0007), <i>to</i> (0.0006), <i>also</i> (0.0001), . . .
join:	<i>join</i> (0.6528), <i>leave</i> (0.2140), <i>oversee</i> (0.0559), <i>head</i> (0.0262), <i>rejoin</i> (0.0074), . . .
the:	<i>its</i> (0.9011), <i>the</i> (0.0981), <i>a</i> (0.0006), . . .
board:	<i>board</i> (0.4288), <i>company</i> (0.2584), <i>firm</i> (0.2024), <i>bank</i> (0.0731), <i>strike</i> (0.0030), . . .

Note that the substitute word distribution for a position (e.g. the second position in Fig. 1) is a function of the context only (i.e. “*the ____ cried*”), and does not depend on the word that actually appears there (i.e. “*man*”). Thus substitute distributions represent *individual word contexts*, not word types. We refer to the use of features based on substitute distributions as *paradigmatic representations of word context*.

We expect words used in similar contexts (with similar substitute distributions) to share the same part-of-speech. Thus part-of-speech induction depends on which contexts are considered similar, and context similarity in turn is a function of the features used to represent word context. Paradigmatic representations, using features of the substitute distribution, uncover latent similarities between contexts that on the surface seem to have little in common. This makes paradigmatic representations more robust to data sparsity, compared to syntagmatic representations which use neighboring words as features. Our empirical results demonstrate that paradigmatic representations significantly outperform syntagmatic ones when compared using similar part-of-speech induction algorithms on identical datasets. Section 2 presents alternative representations of word context and discusses paradigmatic representations in more detail.

2. Representing Word Context

In this section we demonstrate the different contextual representations in the part-of-speech induction (aka. syntactic word categorization) literature and introduce the substitute words as an alternative to the current context representations. In the rest of the paper the words in the vocabulary are referred as *types* and the instances of types are referred as *tokens*.

The contextual representations can be categorized into three groups based on the way they incorporate the local context information of the target type or token: (1) syntagmatic representation, (2) Hidden Markov Models (HMM) and (3) paradigmatic representation. These representations can be further subdivided into two subgroups based on whether they group the types or the tokens.

Syntagmatic Representation. Models with syntagmatic representation group types or tokens according to how similar they are in terms of the co-occurrences with the neighboring tokens (Schütze and Pedersen 1993; Mintz 2003; St Clair, Monaghan, and Christiansen 2010; Lamar et al. 2010; Maron, Lamar, and Bienenstock 2010). Turney and Pantel (2010) give a broad overview of syntagmatic approaches and their applications within the Vector Space Modeling framework. Depending on the way they incorporate co-occurrences these models can group types or tokens.

Schütze (1993) represented the context of a word type by concatenating its left and right co-occurrences vectors. These vectors were calculated for each type by using the left and the right neighbors of the type instances therefore they characterize the distribution of the left and right neighboring tokens of the type. One constraint of this representation is that it represents types rather than tokens thus it is not possible to group the instances of any type into the separate categories.

Mintz (2003) showed on a subset of child directed speech corpus (CHILDES) (MacWhinney 2000) that non-adjacent high frequent bigram frames are useful to the language learners on syntactic categorization of the tokens. For example, the tokens that are observed at “_” in the frame “a _ b” (*a* and *b* are the left and the right bigrams, respectively) are assigned to the same category. Using the top-45 frequent frames Mintz achieved an average of 98% unsupervised accuracy¹. The main limitation of the top-45 frequent frames is that they could only analyze the 6% of the tokens on average due to sparsity. Another drawback is that the tokens with only one common neighbors could not exchange information.

St Clair et al. (2010) extended the work of Mintz (2003) and introduced the flexible bigram frames which represent the context by using the left and the right bigrams separately. As a result tokens with a common left or right bigram might be grouped together whereas the frequent frames categorize the tokens into the same frame if and only if they have same left and right bigrams. For instance, two tokens that are observed at “_” in “a _ b” and “c _ b”, respectively, might be categorized together due to the shared right bigram “b”. Using a feed forward connectionist model they showed that the flexible frames are statistically better than the frequent frames in terms of the supervised accuracy². Moreover they showed that representing token contexts only with the left or the right bigram is statistically better than the frequent frames but worse than the flexible frames in terms of supervised accuracy. Both Mintz (2003) and St Clair (2010) did not report any results with contexts larger than bigrams since as the context is enriched, the re-occurrence frequency of a frame becomes lower which causes the data sparsity (Manning and Schütze 1999).

HMM. Prototypical HMM models assume that each type or token is generated by a latent category and they define the dependencies between the latent categories instead of the tokens as illustrated in Figure ?? (Brown et al. 1992; Blunsom and Cohn 2011; Goldwater and Griffiths 2007; Johnson 2007; Ganchev et al. 2010; Berg-Kirkpatrick and Klein 2010; Lee, Haghighi, and

¹ Unsupervised accuracy was defined as the number of hits (when two intervening tokens observed in the frame from the same category) divided by number of false alarms (when two intervening tokens observed in the frame from different categories).

² The number of analyzed tokens was same in their experiments since they used all the frequent frames instead of the top-45 ones.

Barzilay 2010). As a result instead of directly clustering the words these models try to learn the latent category sequence that generates the given word sequence. The POS induction literature focused on the first and second order HMMs since the higher order HMMs have additional complicating factors³ and require more complex training procedures (Johnson 2007). Depending on the design and the training procedure HMM models can be trained to cluster types or tokens which are detailed in Section 3.

Paradigmatic Representation. In the paradigmatic representation any given context is defined as the distribution of the substitute words in that context. Yatabaz et al. (2012) calculated the most likely substitute words of a word in a given context and grouped the types that have similar substitutes. Schütze (1995) incorporated paradigmatic information by concatenating the left co-occurrence and the right co-occurrence vectors of the right and the left tokens, respectively and grouped the tokens that have similar vectors.

Similarly, Schütze and Pedersen (1993) define the words that frequently co-occur together as the *syntagmatic associates* and words that have similar left and right neighbors as the *paradigmatic parallels*. Turney and Pantel (2010) give a broad overview of syntagmatic approaches and their applications within the Vector Space Modeling framework. We find that representing the paradigmatic axis more directly using substitute vectors rather than frequent neighbors improves part of speech induction.

Sahlgren (2006) gives a detailed analysis of paradigmatic and syntagmatic relations in the context of word-space models used to represent the word meanings. Sahlgren's paradigmatic model represents word types using co-occurrence counts of their frequent neighbors, in contrast to his syntagmatic model that represents word types using counts of contexts (documents, sentences) they occur in. Our substitute vectors do not represent word types at all, but *contexts of word tokens* using probabilities of likely substitutes. Sahlgren finds that in word-spaces built by frequent neighbor vectors, more nearest neighbors share the same part of speech compared to word-spaces built by context vectors.

Our paradigmatic representation is also related to the second order co-occurrences used in (Schütze 1995). Schütze concatenates the left and right context vectors for the target word type with the left context vector of the right neighbor and the right context vector of the left neighbor. The vectors from the neighbors include potential substitutes. Our method improves on his foundation from three aspects: (1) it can cluster both the types and tokens (2) it uses a 4-gram language model rather than bigram statistics, (3) it includes the whole 78,498 word vocabulary rather than the most frequent 250 words. More importantly, rather than simply concatenating the vectors that represent the target word with vectors that represent the context we use a co-occurrence modeling algorithm.

The two examples below illustrate the advantage of paradigmatic representations in uncovering similarities where no overt similarity that can be captured by a syntagmatic representation exists. The word “board” from the first sentence and the word “council” from the second sentence have no common neighbors except the determiner “the”. The paradigmatic representation captures the similarity of these words by suggesting the same top substitutes for both (the numbers in parentheses give substitute probabilities):

- (1) “*Pierre Vinken, 61 years old, will join the **board** as a nonexecutive director Nov. 29.*”
board: board (.4288), company (.2584), firm (.2024), bank (.0731), . . .

³ The number of parameters in a prototypical HMM quadratically increases as the HMM order increases.

(2) "... and hold only 25 % of the seats on the **council** ."

council: board (.6591), company (.0795), firm (.0542), bank (.0154), ...

The high probability substitutes reflect both semantic and syntactic properties of the context. Top substitutes for "board" and "council" are not only nouns, but specifically nouns compatible with the semantic context. Top substitutes for the word "the" in the first example consist of words that can act as determiners: its (.9011), the (.0981), a (.0006), ...

2.1 Computation of Substitute Vectors

In this study, we predict the syntactic category of a word in a given context based on its substitute vector. The dimensions of the substitute vector represent words in the vocabulary, and the entries in the substitute vector represent the probability of those words being used in the given context. Note that the substitute vector is a function of the context only and is indifferent to the target word.

It is best to use both the left and the right context when estimating the probabilities for potential lexical substitutes. For example, in "*He lived in San Francisco suburbs.*", the token *San* would be difficult to guess from the left context but it is almost certain looking at the right context. We define c_w as the $2n - 1$ word window centered around the target word position: $w_{-n+1} \dots w_0 \dots w_{n-1}$ ($n = 4$ is the n -gram order). The probability of a substitute word w in a given context c_w can be estimated as:

$$P(w_0 = w | c_w) \propto P(w_{-n+1} \dots w_0 \dots w_{n-1}) \quad (1)$$

$$= P(w_{-n+1})P(w_{-n+2} | w_{-n+1}) \dots P(w_{n-1} | w_{-n+1}^{n-2}) \quad (2)$$

$$\approx P(w_0 | w_{-n+1}^{-1})P(w_1 | w_{-n+2}^0) \dots P(w_{n-1} | w_0^{n-2}) \quad (3)$$

where w_i^j represents the sequence of words $w_i w_{i+1} \dots w_j$. In Equation 1, $P(w | c_w)$ is proportional to $P(w_{-n+1} \dots w_0 \dots w_{n-1})$ because the words of the context are fixed. Terms without w_0 are identical for each substitute in Equation 2 therefore they have been dropped in Equation 3. Finally, because of the Markov property of n -gram language model, only the closest $n - 1$ words are used in the experiments.

Near the sentence boundaries the appropriate terms were truncated in Equation 3. Specifically, at the beginning of the sentence shorter n -gram contexts were used and at the end of the sentence terms beyond the end-of-sentence token were dropped.

The Wall Street Journal Section of the Penn Treebank (?) was used as the test corpus (1,173,766 tokens, 49,206 types) to be induced. The treebank uses 45 part-of-speech tags which is the set we used as the gold standard for comparison in our experiments. To compute substitute probabilities we trained a language model using approximately 126 million tokens of Wall Street Journal data (1987-1994) extracted from CSR-III Text (Graff, Rosenfeld, and Paul 1995) (excluding sections of the PTB). We used SRILM (Stolcke 2002) to build a 4-gram language model with Kneser-Ney discounting. Words that were observed less than 20 times in the language model training data were replaced by UNK tags, which gave us a vocabulary size of 78,498. The perplexity of the 4-gram language model on the test corpus is 96.

3. Part-of-speech Induction

There are several good reviews of algorithms for unsupervised part of speech induction (Christodoulopoulos, Goldwater, and Steedman 2010; Gao and Johnson 2008) and models of syntactic category acquisition (Ambridge and Lieven 2011).

This work is to be distinguished from supervised part of speech disambiguation systems, which use labeled training data (Toutanova et al. 2003), unsupervised disambiguation systems, which use a dictionary of possible tags for each word (Yatbaz and Yuret 2010), or prototype driven systems which use a small set of prototypes for each class (Haghighi and Klein 2006). The problem of induction is important for studying under-resourced languages that lack labeled corpora and high quality dictionaries. It is also essential in modeling child language acquisition because every child manages to induce syntactic categories without access to labeled sentences, labeled prototypes, or dictionary constraints.

Models of unsupervised part of speech induction fall into two broad groups based on the information they utilize. Distributional models only use word types and their context statistics. Word-feature models incorporate additional morphological and orthographic features.

3.1 Distributional models

Distributional models can be further categorized into three subgroups based on the learning algorithm. The first subgroup represents each word type/token with its context vector and clusters these vectors accordingly (Schütze 1995). Work in modeling child syntactic category acquisition has generally followed this clustering approach (Redington, Crater, and Finch 1998; Mintz 2003). The second subgroup consists of probabilistic models based on the Hidden Markov Model (HMM) framework (Brown et al. 1992). A third group of algorithms constructs a low dimensional representation of the data that represents the empirical co-occurrence statistics of word types (Globerson et al. 2007), which is covered in more detail in Section 4.

Clustering. Clustering based methods represent the context using the neighboring words, typically a single word on the left and a single word on the right called a “frame” (e.g., **the dog is; the cat is**). They cluster word types rather than word tokens based on the frames they occupy thus employing one-tag-per-word assumption from the beginning (with the exception of (Mintz 2003; St Clair, Monaghan, and Christiansen 2010) and some methods in (Schütze 1995)). They may suffer from the data sparsity caused by the infrequent words and the infrequent contexts. The solutions suggested either restrict the set of words and set of contexts to be clustered to the most frequently observed, or use dimensionality reduction. Redington et al. (1998) define context similarity based on the number of common frames bypassing the data sparsity problem but achieve lower scores than the best performing systems. Mintz (2003) only uses the most frequent 45 frames to cluster tokens and achieves 98% unsupervised accuracy on the tokens observed in the most frequent 45 frames. Similar to Mintz’s work, St Clair et al. (2010) show that systems that model the left and right frames of tokens separately perform better than the frequent frames both in terms of token clustering accuracy and the token coverage. Biemann (2006) constructs a graph based view of the most frequent 10,000 words using contexts formed from the most frequent 150-200 words and clusters the tokens. Schütze (1995) and Lamar et al. (2010) employ SVD to enhance similarity between less frequently observed word types and contexts. Lamar et al. (2010) represent each context by the currently assigned left and right tag (which eliminates data sparsity) and cluster word types using a soft k-means style iterative algorithm. They report the best clustering result to date of .708 many-to-one accuracy on the PTB.

HMMs. The prototypical bitag HMM model maximizes the likelihood of the corpus $w_1 \dots w_n$ expressed as $P(w_1|c_1) \prod_{i=2}^n P(w_i|c_i)P(c_i|c_{i-1})$ where w_i are the word tokens and c_i are their (hidden) tags. One problem with such a model is its tendency to distribute probabilities equally and the resulting inability to model highly skewed word-tag distributions observed in hand-labeled data (Johnson 2007). To favor sparse word-tag distributions one can enforce a strict one-tag-per-word solution (type clustering) (Brown et al. 1992; Clark 2003), use sparse priors in a Bayesian setting (Goldwater and Griffiths 2007; Johnson 2007), or use posterior regularization (Ganchev et al. 2010). Each of these techniques provide significant improvements over the standard HMM model: for example Gao and Johnson (2008) show that sparse priors can gain from 4% (.62 to .66 on the PTB) in cross-validated many-to-one accuracy. However Christodoulopoulos et al. (2010) show that the older one-tag-per-word models such as (Brown et al. 1992) outperform the more sophisticated sparse prior and posterior regularization methods both in speed and accuracy (the Brown model gets .68 many-to-one accuracy on the PTB). Given that 93.69% of the word occurrences in human labeled data are tagged with their most frequent part of speech (Toutanova et al. 2003), this is probably not surprising; one-tag-per-word is a fairly good first approximation for induction.

3.2 Word-feature models

One problem with the algorithms in the previous section is the poverty of their input features. Of the syntactic, semantic, and morphological information linguists claim underlie syntactic categories, context vectors or bitag HMMs only represent limited syntactic information in their input. Experiments incorporating morphological and orthographic features into HMM based models demonstrate significant improvements. (Clark 2003; Berg-Kirkpatrick and Klein 2010; Blunsom and Cohn 2011) incorporate similar orthographic features and report improvements of 3, 7, and 10% respectively over the baseline Brown model.

(Clark 2003; Blunsom and Cohn 2011) cluster types by incorporating similar orthographic features and report improvements of 3 and 10% respectively over the baseline Brown model. Berg-Kirkpatrick et al. incorporate orthographic features into EM algorithm where they replace the multinomial components with miniature logistic regressions and cluster tokens while improving the Brown model by 7%.

Christodoulopoulos et al. (2010) use prototype based features as described in (Haghighi and Klein 2006) with automatically induced prototypes and report an 8% improvement over the baseline Brown model by clustering tokens. Abend et al. (2010) train a prototype-driven model with morphological features by first clustering the high frequent types as the landmarks and then assigning the remaining types to these landmark clusters. Christodoulopoulos et al. (2011) define a type-based Bayesian multinomial mixture model in which each word instance is generated from the corresponding word type mixture component and word contexts are represented as features. They achieve a .728 MTO score by extending their model with additional morphological and alignment features gathered from parallel corpora. To our knowledge, nobody has yet tried to incorporate phonological or prosodic features in a computational model for syntactic category acquisition.

3.3 Paradigmatic representations

Yatbaz et al. (2012) explore the paradigmatic representation of the word contexts by modeling the co-occurrence of words and their substitutes within the CODE framework. Their experiments on the PTB types shows that paradigmatic representation improves the state-of-the-art MTO and V-measure (VM) accuracies of both distributional models and models with additional word features. This paper builds on that preliminary work by (1) exploring clustering of substitute

vectors, (2) improving the model for using additional features, and (3) experimenting with additional languages.

3.4 Evaluation

We report many-to-one and V-measure scores for our experiments as suggested in (Christodoulopoulos, Goldwater, and Steedman 2010). The many-to-one (MTO) evaluation maps each cluster to its most frequent gold tag and reports the percentage of correctly tagged instances. The MTO score naturally gets higher with increasing number of clusters but it is an intuitive metric when comparing results with the same number of clusters. The V-measure (VM) (Rosenberg and Hirschberg 2007) is an information theoretic metric that reports the harmonic mean of homogeneity (each cluster should contain only instances of a single class) and completeness (all instances of a class should be members of the same cluster). In Section 9 we argue that homogeneity is perhaps more important in part of speech induction and suggest MTO with a fixed number of clusters as a more intuitive metric.

4. Co-occurrence Modeling

In this section we combine the paradigmatic representation of the word context with the identity and features of the target word for part of speech induction using a co-occurrence modeling framework. Our preliminary experiments in Section ?? indicated that using the context information alone (e.g. clustering substitute vectors) without the target word identity and features had limited success. Moreover incorporating word identities (i.e. the one-tag-per-word constraint) even in an ad-hoc manner by re-tagging the clustering output significantly improves the MTO accuracy. It seems that the co-occurrence of a target word with a particular type of context may be a better predictor of the syntactic category.

Section 4.1 reviews the unsupervised methods we use to model co-occurrence statistics: the Co-occurrence Data Embedding (CODE) (Globerson et al. 2007) method and its spherical extension (S-CODE) introduced by (Maron, Lamar, and Bienenstock 2010). Section 5.1 describes the general experimental settings. The S-CODE algorithm works with discrete inputs. The substitute vectors as described in Section ?? are high dimensional and continuous. We experimented with two approaches to use substitute vectors in a discrete setting. Section 5.2 presents an algorithm that partitions the high dimensional space of substitute vectors into small neighborhoods and uses the partition id as a discrete context representation. Section 5.3 presents an even simpler model which pairs each word with random substitutes sampled from the substitute vector. Section 5.4 replicates the bigram based S-CODE results from (Maron, Lamar, and Bienenstock 2010) as a direct comparison of paradigmatic vs syntagmatic representations of word context. When the left-word – right-word pairs used in the bigram model are replaced with word – partition-id or word – substitute pairs we see significant gains in accuracy. These results support our running hypothesis that paradigmatic features, i.e. potential substitutes of a word, are better determiners of syntactic category compared to left and right neighbors (syntagmatic features). Section 7 explores morphological and orthographic features as additional sources of information and its results improve the state-of-the-art in the field of unsupervised part of speech induction.

4.1 The CODE Model

Let X and Y be two categorical variables with finite cardinalities $|X|$ and $|Y|$. We observe a set of pairs $\{x_i, y_i\}_{i=1}^n$ drawn IID from the joint distribution of X and Y . The basic idea behind CODE and related methods is to represent (embed) each value of X and each value of Y as points in a common low dimensional Euclidean space \mathbf{R}^d such that values that frequently co-occur lie

close to each other. There are several ways to formalize the relationship between the distances and co-occurrence statistics, in this paper we use the following:

$$p(x, y) = \frac{1}{Z} \bar{p}(x) \bar{p}(y) e^{-d_{x,y}^2} \quad (4)$$

where $d_{x,y}^2$ is the squared distance between the embeddings of x and y , $\bar{p}(x)$ and $\bar{p}(y)$ are empirical probabilities, and $Z = \sum_{x,y} \bar{p}(x) \bar{p}(y) e^{-d_{x,y}^2}$ is a normalization term. If we use the notation ϕ_x for the point corresponding to x and ψ_y for the point corresponding to y then $d_{x,y}^2 = \|\phi_x - \psi_y\|^2$. The log-likelihood of a given embedding $\ell(\phi, \psi)$ can be expressed as:

$$\begin{aligned} \ell(\phi, \psi) &= \sum_{x,y} \bar{p}(x, y) \log p(x, y) \\ &= \sum_{x,y} \bar{p}(x, y) (-\log Z + \log \bar{p}(x) \bar{p}(y) - d_{x,y}^2) \\ &= -\log Z + \text{const} - \sum_{x,y} \bar{p}(x, y) d_{x,y}^2 \end{aligned} \quad (5)$$

The likelihood is not convex in ϕ and ψ . We use gradient ascent to find an approximate solution for a set of ϕ_x, ψ_y that maximize the likelihood. The gradient of the $d_{x,y}^2$ term pulls neighbors closer in proportion to the empirical joint probability:

$$\frac{\partial}{\partial \phi_x} \sum_{x,y} -\bar{p}(x, y) d_{x,y}^2 = \sum_y 2\bar{p}(x, y) (\psi_y - \phi_x) \quad (6)$$

The gradient of the Z term pushes neighbors apart in proportion to the estimated joint probability:

$$\frac{\partial}{\partial \phi_x} (-\log Z) = \sum_y 2p(x, y) (\phi_x - \psi_y) \quad (7)$$

Thus the net effect is to pull pairs together if their estimated probability is less than the empirical probability and to push them apart otherwise. The gradients with respect to ψ_y are similar.

S-CODE (Maron, Lamar, and Bienenstock 2010) additionally restricts all ϕ_x and ψ_y to lie on the unit sphere. With this restriction, Z stays around a fixed value during gradient ascent. This allows S-CODE to substitute an approximate constant \tilde{Z} in gradient calculations for the real Z for computational efficiency. In our experiments, we used S-CODE with its sampling based stochastic gradient ascent algorithm and smoothly decreasing learning rate.

5. POS Induction for Word Types

5.1 Experimental Settings

To make a meaningful comparison on the PTB we ran all the experiments using the following default settings (unless otherwise stated): (i) each word was kept with its original capitalization, (ii) the learning rate parameters were set to $\varphi_0 = 50$, $\eta_0 = 0.2$ for faster convergence in log likelihood, (iii) the number of S-CODE iterations were set to 50 million, (iv) the S-CODE dimensions and Z were set to 25 and 0.166, respectively, (v) a modified k-means algorithm with

Table 2

Summary of results in terms of the MTO and VM scores. Standard errors are given in parentheses when available. Starred entries have been reported in the review paper (Christodoulopoulos, Goldwater, and Steedman 2010). Distributional models use only the identity of the target word and its context. The models on the right incorporate orthographic and morphological features.

Distributional Models	MTO	VM	Models with Additional Features	MTO	VM
Lamar et al. (2010)	.708	-	Clark (2003)*	.712	.655
Brown et al. (1992)*	.678	.630	Christodoulopoulos et al. (2011)	.728	.661

Ganchev et al. (2010)*	.625	.548	Christodoulopoulos et al. (2010)	.761	.688
Maron et al. (2010)	.688 (.0016)	-	Blunsom and Cohn (2011)	.775	.697
Substitutes(Tokens) (Sec. 6)			Substitutes and Features (Sec. 7)	.8002 (.0066)	.7163 (.0038)
Bigrams (Sec. 5.4)	.7314 (.0096)	.6558 (.0052)			
Substitutes(Types) (Sec. 5.3)	.7667 (.0050)	.6819 (.0026)			

smart initialization was used (Arthur and Vassilvitskii 2007), and (vi) the number of k-means restarts were set to 128 to improve clustering and reduce variance.

For computational efficiency only the top 100 substitutes and their unnormalized probabilities were computed for each positions in the PTB (1,173,766 tokens, 49,206 types) using the FASTSUBS algorithm (Yuret 2012)⁴. The probability vectors for each position were normalized to add up to 1.0 giving us the final substitute vectors used in the rest of this study.

Each experiment was repeated 10 times with different random seeds and the results are reported with standard errors in parentheses or error bars in graphs. Table 2 summarizes all the results reported in this section and the ones we cite from the literature.

5.2 Random Substitutes

To obtain a discrete representation of the context, the random-substitutes algorithm pairs each word token with a substitute sampled from the pre-computed substitute vectors generated from the word token’s context (see Section ??) and word (X) – random-substitute (Y) pairs are fed to the S-CODE as input. It is possible (and beneficial, see below) to run the random-substitutes algorithm on the data more than once to generate more pairs from the same substitute vectors. The S-CODE uses stochastic gradient ascent to find the ϕ_x, ψ_y embeddings for word and random-substitute in these pairs on a single 25-dimensional sphere. The algorithm cycles through the data until we get approximately 50 million updates. The resulting ϕ_x vectors are clustered using an instance weighted k-means algorithm. Cluster-id for each ϕ_x is assigned as the predicted cluster-id for word type X . Using the default settings and sampling 64 substitutes for each token the many-to-one accuracy is .7667 (.0050) and the V-measure is .6819 (.0026).

To analyze the sensitivity of this result to our specific parameter settings we ran a number of experiments where each parameter was varied over a range of values.

Figure 5 illustrates that the random-substitute result is fairly robust as long as the training algorithm can observe more than a few random substitutes per word.

Figure 3 shows that at least 10 embedding dimensions are necessary to get within 1% of the best result, but there is no significant gain from using more than 25 dimensions.

Figure 4 shows that the constant \tilde{Z} approximation can be varied within two orders of magnitude without a significant performance drop in the many-to-one score. For uniformly distributed points on a 25 dimensional sphere, the expected $Z \approx 0.146$. In the experiments where

⁴ The substitutes with unnormalized log probabilities can be downloaded from <http://goo.gl/jzKH0>.

**Figure 2**

MTO is not sensitive to the number of random substitutes sampled per word token.

**Figure 3**

MTO falls sharply for less than 10 S-CODE dimensions, but more than 25 do not help.

**Figure 4**

MTO is fairly stable as long as the \tilde{Z} constant is within an order of magnitude of the real Z value.

we tested we found the real Z always to be in the 0.140-0.170 range. When the constant \tilde{Z} estimate is too small the attraction in Eq. 6 dominates the repulsion in Eq. 7 and all points tend to converge to the same location. When \tilde{Z} is too high, it prevents meaningful clusters from coalescing.

We find the random substitute algorithm to be fairly robust to different parameter settings and the resulting many-to-one score significantly better than the state-of-the-art distributional models.

5.3 Paradigmatic vs Syntagmatic Representations of Word Context

To get a direct comparison of the paradigmatic and syntagmatic context representations we feed the adjacent word pairs (bigrams) in the corpus into the S-CODE algorithm as X, Y samples (Maron, Lamar, and Bienenstock 2010) instead of pairing each word with a paradigmatic representation of its context. At the end each word w in the vocabulary ends up with two points on the sphere, a ϕ_w point representing the behavior of w as the left word of a bigram and a ψ_w point representing it as the right word. The two vectors for w are concatenated to create a 50-dimensional representation at the end. These 50-dimensional vectors are clustered using the k-means algorithm. Maron et al. (2010) report many-to-one scores of .6880 (.0016) for 45 clusters and .7150 (.0060) for 50 clusters (on the PTB). If only ϕ_w vectors are clustered without concatenation we found the performance drops significantly to about .62. Using our default settings the bigram model achieves .7314 (.0096) MTO and .6558 (.0052) VM accuracies. Both results are significantly lower than the random substitute MTO and VM accuracies.

6. POS Induction for Word Tokens

In this section, we extend the random-substitutes algorithm presented earlier to perform POS induction for the word tokens rather than word types. We use the same settings in the Section 5.3 and generate word (X) – random-substitute (Y) pairs as the input to the S-CODE. For each observed $X - Y$ pair in the S-CODE input, corresponding 25-dimensional ϕ_x and ψ_y embedding vectors are concatenated to create a 50-dimensional representation. The resulting 50-dimensional vectors are clustered using the instance weighted k-means algorithm (with fewer restarts to accommodate the input size). The process yields 64 cluster-ids (for every pair generated from word token's context) for each word token's context. The word tokens' cluster-ids are predicted by the majority cluster-id of the corresponding pairs. Ties for the majority are broken randomly. The many-to-one accuracy is . and the V-measure is .

7. Morphological and orthographic features

Clark (2003) demonstrates that using morphological and orthographic features significantly improves part of speech induction with an HMM based model. Section 3 describes a number of other approaches that show similar improvements. This section describes one way to integrate additional features to the random-substitute model.

In order to accommodate multiple feature types the CODE model needs to be extended to handle more than two variables. Globerson et al. (2007) suggest the following likelihood function:

$$\ell(\phi, \psi^{(1)}, \dots, \psi^{(K)}) = \sum_i^K w_i \sum_{x, y^{(i)}} \bar{p}(x, y^{(i)}) \log p(x, y^{(i)}) \quad (8)$$

where $Y^{(1)}, \dots, Y^{(K)}$ are K different variables whose empirical joint distributions with X , $\bar{p}(x, y^{(1)}) \dots \bar{p}(x, y^{(K)})$, are known. Eq. 8 then represents a set of CODE models $p(x, y^{(k)})$ where each $Y^{(k)}$ has an embedding $\psi_y^{(k)}$ but all models share the same ϕ_x embedding. The

weights w_k reflect the relative importance of each $Y^{(k)}$ and all embeddings are mapped to unit-sphere.

We adopt this likelihood function, set all $w_k = 1$, let X represent a word, $Y^{(1)}$ represent a random substitute, and $Y^{(2)}, \dots, Y^{(K)}$ stand for morphological and orthographic features of the word thus each word is a $(K+1)$ -tuple, $(X, Y^{(1)}, \dots, Y^{(K)})$. With this setup, the training procedure needs to change little: instead of sampling a word – random-substitute pair, the word – random-substitute – features tuple is sampled and input to the gradient ascent algorithm. The gradient search algorithm updates the embeddings according to $p(x, y^{(i)})$ where $i = 1 \dots k$ and no updates are performed between $y^{(i)}$ s since they do not have any co-occurrence statistics and x is the shared variable.

Word tuples might have null values due to the unobserved features. For example, the word “car” has no morphological or orthographic features therefore all the elements of the tuple have null value except the word type (X) and the random-substitute ($Y^{(1)}$). We do not perform any pull or push updates on embeddings during the gradient search if the corresponding $y^{(k)}$ is null⁵.

The orthographic features we used are similar to the ones in (Berg-Kirkpatrick et al. 2010) with small modifications:

- Initial-Capital: this feature is generated for capitalized words with the exception of sentence initial words.
- Number: this feature is generated when the token starts with a digit.
- Contains-Hyphen: this feature is generated for lowercase words with an internal hyphen.
- Initial-Apostrophe: this feature is generated for tokens that start with an apostrophe.

We generated morphological features using the unsupervised algorithm Morfessor (Creutz and Lagus 2005). Morfessor was trained on the WSJ section of the Penn Treebank using default settings, and a perplexity threshold of 1. In our model, a word type consists of two parts: a stem and a suffix part. The suffix part is used as the morphological feature thus each word type has only one morphological feature⁶. The program induced 5575 suffix types that are present in a total of 19223 word types.

Using the training settings of the previous section, the addition of morphological and orthographic features increased the many-to-one score of the random-substitute model to .8002 (.0066) and V-measure to .7163 (.0038). Both these results improve the state-of-the-art in part of speech induction significantly as seen in Table 2.

8. Multilingual Experiments

We performed experiments with a range of languages and three different feature configurations to establish both the robustness of our model across languages and to observe the effects of different features. Following Christodoulopoulos et al. (2011), in addition to the PTB we extend our experiments to 8 languages from MULTEXT-East (Bulgarian, Czech, English, Estonian, Hungarian, Romanian, Slovene and Serbian) (Erjavec 2004) and 10 languages from the CoNLL-X shared task (Bulgarian, Czech, Danish, Dutch, German, Portuguese, Slovene, Spanish, Swedish and

⁵ X and $Y^{(1)}$ represents the word type and random-substitute therefore they are always observed.

⁶ We extracted the stem part by concatenating the splits until including the first “STM” labeled split and the suffix part by concatenating rest of the splits.

Turkish) (Buchholz and Marsi 2006). For all experiments, we use the best performing model of Section 4 (i.e. the random substitute model) with default settings. To perform meaningful comparisons with the previous work we train and evaluate our models on the training section of MULTEXT-East⁷ and CONLL-X languages (Lee, Haghighi, and Barzilay 2010).

Section 8.1 details the language model and feature statistics of each language. Section 8.2 summarizes the results of our models for all of the languages in our corpora. In the rest of this section we refer to the MULTEXT-East and CONLL-X corpora as the testing corpora and the language model training corpora as the training corpora.

8.1 Substitute Vectors and Features

Table 3

Summary of language model training and test corpora statistics for each language in the test set. Last two columns present the number of induced suffix parts and word types with these suffix parts after the morphological feature extraction.

To calculate the top 100 substitutes of each position, we train a 4-gram language model with the corresponding training corpora of each language as described in Section 5.1. Table 3 presents statistics related to the language model training and testing corpora. For all languages

⁷ Languages of MULTEXT-East corpora do not tag the punctuation marks, thus we add an extra tag for punctuation to the tag-set of these languages.

except Serbian, English and Turkish, we train the language models by using the corresponding Wikipedia dump files⁸.

Serbian shares a common basis with Croatian and Bosnian therefore we trained 3 different language models using Wikipedia dump files of Serbian together with these two languages and measured the perplexities on the MULTEXT-East Serbian corpus. We chose the Croatian language model since it achieved the lowest perplexity score and unknown word ratio on the MULTEXT-East Serbian corpus.

To train the statistical language model of English, we use Wall Street Journal data (1987-1994) extracted from CSR-III Text (Graff, Rosenfeld, and Paul 1995) (excluding sections of the PTB) and for the Turkish language modeling we use the web corpus collected from Turkish news and blog sites (Sak, Güngör, and Saraçlar 2008).

Language model training files vary across the languages in terms of quality and quantity. In order to reduce the unknown word ratio of resource poor languages and to standardize the process we set the vocabulary threshold to 2 for all languages except English. English has relatively low unknown word ratio therefore we set the threshold to 20 instead of 2.

We use the same set of orthographic features described in Section 7 except we add an “Only-Punctuation” feature to the languages of MULTEXT-East corpora. The “Only-Punctuation” feature is generated when a token only consists of punctuation characters.

Morphological features are extracted by the method described in Section 7 using the training sections of each language in MULTEXT-East and CoNLL-X corpora⁹. Language specific morphological feature statistics are summarized in Table 3.

8.2 Results

For each language we report results of three models: (1) distributional (DIS), (2) distributional with orthographic features (DIS+O) and (3) distributional with both orthographic and morphological features (DIS+O+M). Similar to the settings used in Section 5.3, we use the 25 dimensional sphere with 64 substitutes for all languages. For each language the number of induced clusters is set to the number of tags in the gold-set as presented in Table 4.

As a baseline model we chose the syntagmatic bigram version of S-CODE described in Section 5.4 which is a very strong baseline compared to the ones used in (Christodoulopoulos, Goldwater, and Steedman 2011). Table 4 summarizes the MTO and VM scores of our models together with the syntagmatic bigram baseline and the best published accuracies on each language corpus.

DIS significantly outperforms the syntagmatic bigram baseline in both MTO and VM scores on 14 languages. DIS+O+M has the state-of-the-art MTO and VM accuracy on the PTB. DIS+O and DIS+O+M achieve the highest MTO scores on all languages of MULTEXT-East corpora while scoring the highest VM accuracies on English and Romanian. On the CoNLL-X languages our models perform better than the best published MTO or VM accuracies on 10 languages.

9. Discussion

In this section we perform further analysis on the clustering output of our best model and indicate the possible reasons of comparably low VM scores. To illustrate how words are distributed in the

⁸ Latest Wikipedia dump files are freely available at <http://dumps.wikimedia.org/> and the text in the dump files can be extracted using WP2TXT (<http://wp2txt.rubyforge.org/>)

⁹ We don’t use the language model corpora to extract morphological features.

Table 4

The MTO and VM scores on 19 corpora in 15 languages together with the number of types and tags in gold-set which equals to number of induced clusters in all languages. Best published results are from [‡](Blunsom and Cohn 2011), ^{*}(Christodoulopoulos, Goldwater, and Steedman 2011) and [†](Clark 2003). Bold results represent the best MTO and VM accuracies of the corresponding language. MULTEXT-East corpora do not tag the punctuation marks, thus we add an extra tag for punctuation and represent it with “+I”.

	Language	Types	Tags	Best Published	Syntagmatic Bigram	DIS	DIS+O	DIS+O+M

induced clusters, we compare the output of our model with gold-tags of the PTB. We also discuss the effect of coarse gold-tag sets on our model performance.

Figure 6 is the Hinton diagram of the PTB showing the relationship between the most frequent tags and clusters from the experiment in Section 7. In general the errors seem to be the lack of completeness (multiple large entries in a row), rather than lack of homogeneity (multiple large entries in a column). The algorithm tends to split large word classes into several clusters. Some examples are:

- Titles like Mr., Mrs., and Dr. are split from the rest of the proper nouns in cluster (39).
- Auxiliary verbs (10) and the verb “say” (22) have been split from the general verb clusters (12) and (7).
- Determiners “the” (40), “a” (15), and capitalized “The”, “A” (6) have been split into their own clusters.
- Prepositions “of” (19), and “by”, “at” (17) have been split from the general preposition cluster (8).

Nevertheless there are some homogeneity errors as well:

**Figure 5**

Hinton diagram comparing most frequent tags and clusters. Area of each square is proportional to the joint probability of the given tag and cluster.

- The adjective cluster (5) also has some noun members probably due to the difficulty of separating noun-noun compounds from adjective modification.
- Cluster (6) contains capitalized words that span a number of categories.

Most closed-class items are cleanly separated into their own clusters as seen in the lower right hand corner of the diagram.

The completeness errors become more noticeable on languages with coarse tag-sets thus our models perform worse than the best published models on 6 of MULTEXT-East languages in terms of VM scores while achieving the state-of-the-art MTO scores on same languages as shown on Table 4. On CONLL-X languages the effect of completeness errors is less noticeable since all languages except Czech and Dutch have fine grained tag-sets.

The completeness errors are not surprising given that the words that have been split are not generally substitutable with the other members of their gold-tag set category. Thus it can be argued that metrics that emphasize homogeneity such as MTO are more appropriate in this context than metrics that average homogeneity and completeness such as VM as long as the number of clusters is controlled.

There are two concerns inherent in all distributional methods: (i) words that are generally substitutable like “the” and “its” are placed in separate categories (DT and PRP\$) by the gold standard, (ii) words that are generally not substitutable like “do” and “put” are placed in the same category (VB). Freudenthal et al. (2005) point out that categories with unsubstitutable words fail the standard linguistic definition of a syntactic category and children do not seem to make errors of substituting such words in utterances (e.g. “*What do you want?*” vs. *“*What put you want?*”). Whether gold standard part of speech tags or distributional categories are better suited to applications like parsing or machine translation can be best decided using extrinsic evaluation. In this study we evaluate our results by comparing them to gold standard part of speech tags and leave the extrinsic evaluation of the induced tags for future work.

10. Contributions

Our main contributions can be summarized as follows:

- We introduced substitute vectors as paradigmatic representations of word context and demonstrated their use in unsupervised part of speech induction on 19 corpora in 15 languages.
- We demonstrated that using paradigmatic representations of word context and modeling co-occurrences of word and context types with the S-CODE learning framework give superior results when compared to a syntagmatic bigram model.
- We extended the S-CODE framework to incorporate morphological and orthographic features and improved the state-of-the-art many-to-one accuracy in unsupervised part of speech induction on 17 out of 19 corpora.
- All our code and data, including the substitute vectors for the PTB, MULTEXT-East and CoNLL-X shared task corpora are available at the authors' website at `xxx.xxx.xxx`.
